Abstract

We present two novel algorithms for constructing spatial hierarchies on GPUs. The first is for kd-trees that automatically balances between the level of parallelism and total memory usage by using a novel PBFS (partial breadth-first search) construction scheme. With this PBFS construction scheme, peak memory consumption can be efficiently controlled without costly CPU-GPU data transfer. We also develop memory allocation strategies to effectively limit memory fragmentation. The resulting algorithm scales well with GPU memory and constructs kd-trees of models with millions of triangles at interactive rates on GPUs with 1GB memory. Compared with existing algorithms, our algorithm is an order of magnitude more scalable for a given GPU memory bound.

The second algorithm is for out-of-core BVH (bounding volume hierarchy) construction for very large scenes based on the PBFS construction order. At each iteration, all constructed nodes are dumped to the CPU memory, and the GPU memory is freed for the next iteration's use. In this way, the algorithm is able to build trees that are too large to be stored in the GPU memory. Experiments show that our algorithm can construct BVHs for scenes with up to 20M triangles, several times larger than previous GPU algorithms.

Keywords: memory bound, kd-tree, bounding volume hierarchy

Figure 1: *Kd-tree construction and ray tracing of two large animated scenes. (a) 7,140K triangles, 612 instances of three models each of which has 5K-20K triangles. (b) 6,763K triangles, a terrain and 135 instances of three skinning meshes each of which has 17K-85K triangles. For each scene, at each frame, we construct a kd-tree and use it to ray trace the scene completely on the GPU. Images are rendered at* 1024×1024 *resolution with 4 point lights. Note that object instancing is solely used to simplify animation production and is not exploited by the kd-tree constructor.*

1 Introduction

Current many-core GPUs have evolved into incredible computing processors for general purpose computation, and this evolution is likely to continue in the future. Recently, GPU construction of hierarchical data structures such as kd-trees [Zhou et al. 2008] and BVHs [Lauterbach et al. 2009] has shown great promise in a variety of applications, including ray tracing, photon mapping, point cloud modeling and simulations. Unlike traditional CPU-based algorithms, which build hierarchical data structures following the DFS (depth-first search) order, the GPU algorithms achieve interactive construction by using the BFS (breadth-first search) order, which best exploits the massive parallelism on the GPU. These algorithms exploit the multiple cores and high memory bandwidth in terms of building hierarchies of complex models at interactive rates. Unfortunately, this parallel computation comes at the cost of excessive memory consumption overhead because the GPU algorithms need to maintain and process a large amount of data simultaneously. This becomes a serious issue for interactive applications involving complex models with more than few million triangles [Zhou et al. 2008; Lauterbach et al. 2009]. Current GPUs have a different memory architecture than CPUs. The on-chip memory on GPUs is limited to a few GBs. Moreover, GPUs have high memory bandwidth and much smaller caches. As a result, it is important to design GPU-based algorithms that can exploit these memory architecture characteristics of GPUs for interactive applications.

In this paper, we first present a GPU kd-tree algorithm that achieves superior performance for a given memory bound. Our algorithm automatically adapts the level of parallelism based on available memory and thus allows the peak memory consumption to be controlled without swapping any data out of the GPU. The basic idea is to construct the kd-tree in a PBFS (partial breadth-first search) order. Unlike the BFS and DFS, the PBFS allows the set of tree nodes being processed simultaneously to be explicitly controlled in each iteration, and thereby enables management of the memory overhead and level of parallelism. By fine tuning the set of nodes being processed simultaneously, we can achieve a good balance between them. Note that the PBFS only affects the order of node processing and does not impact the quality of the resulting tree. On an NVIDIA GeForce GTX 280 GPU with 1 GB memory, we can construct kd-trees of scenes with up to several million triangles at interactive rates.

Our second contribution is an out-of-core BVH construction algorithm on the GPU. Compared to kd-tree construction, BVH construction has a relatively small memory overhead. It does not split triangles and does not need to dynamically allocate GPU memory. Consequentially, the primitive storage remains static throughout the construction and the final tree size can be bounded prior to construction. However, the memory consumption will still exceed the available GPU memory for very large scenes. Our BVH builder is also based on PBFS construction order. At each PBFS iteration, all constructed nodes are dumped to the CPU memory or disk, and the GPU memory is freed for the next iteration's use. In this way, the algorithm is able to build trees that are too large to be stored in the GPU memory. Our algorithm can construct BVHs for scenes with up to 20M triangles.

As far as we know, ours are the first GPU hierarchy construction algorithms that are designed with a memory bound in mind. Our methods can handle scenes nearly an order of magnitude larger than previous GPU methods. For small scenes that previous GPU methods can handle, our algorithm achieves similar construction performance. For large scenes, our method performs comparably to the state-of-the-art multi-core CPU algorithms in terms of construction time while maintaining tree quality similar to high quality methods. In general our methods scale well with respect to the

amount of available memory, and hierarchy construction can be performed within user-specified memory bounds at a modest performance cost.

We will briefly review previous work relevant to fast spatial hierarchy construction in Section 2. In Section 3, we describe our memory-scalable kd-tree construction algorithm. Section 4 describes how to use the PBFS order to support out-of-core BVH construction on the GPU. Finally, we present results in Section 5.

2 Related Work

Several CPU-based algorithms have been proposed for fast construction of SAH (surface area heuristic) kd-trees [Goldsmith and Salmon 1987; MacDonald and Booth 1990], which are commonly regarded to offer optimal ray tracing performance. Hunt et al. [2006] approximated the SAH cost function to achieve sub-interactive construction with minimal degradation in tree quality. Shevtsov et al. [2007] developed an interactive parallel construction algorithm with a modest memory footprint on multi-core CPUs. However, their tree suffers from considerable quality loss. Soupikov et al. [2008] recently introduced approximate triangle clipping to compensate for this quality loss within a similar construction time. However with both algorithms, tests show serious scalability issues at more than a few hundred threads. This makes them inappropriate for massively parallel architectures like GPUs.

Zhou et al. [2008] proposed the first kd-tree construction that runs entirely on the GPU. The algorithm maximizes parallelism in the construction process and scales well to GPUs with hundreds of cores. High quality trees can be constructed in rapid time. However, the high parallelism is achieved at the cost of excessive memory consumption. This results in a scene size limitation one order of magnitude smaller than previous methods. We use the node splitting schemes of [Zhou et al. 2008] to maintain tree quality and construction performance but introduce novel parallelization and memory management techniques to bound the memory consumption.

BVH is an alternative spatial hierarchy for ray tracing that favors build time over tracing performance. Efficient construction has been demonstrated on both CPU and GPU [Wald 2007; Wald et al. 2008; Lauterbach et al. 2009]. Recent work also demonstrates ray tracing performance improvement by incorporating kd-tree-like features into BVHs [Ernst and Greiner 2007]. The state-of-the-art GPU BVH construction algorithm [Lauterbach et al. 2009] has a work-flow resembling GPU kd-tree construction. We apply the the PBFS construction order to the hybrid algorithm described in [Lauterbach et al. 2009] for out-of-core BVH construction of very large scenes.

Wachter and Keller [2007] tackled the memory problem of kd-trees from a different perspective. They terminated the splitting node when necessary to bound the final hierarchy size. Their approach puts the tree quality at risk and does not apply to hierarchies with naturally bounded size like BVH. In contrast, our work seeks to control the work memory requirement during construction while maintaining tree quality. Paging systems like virtual memory can be used to handle large data within limited physical memory, effectively providing out-of-core support for any algorithm. Built-in virtual memory support can be expected in future GPUs such as Larrabee [Seiler et al. 2008]. A general paging-like out-of-core system also has been demonstrated on current hardware [Budge et al. 2009]. While paging systems can be very efficient when handling large input/output, paging intermediate work memory can result in significant performance overhead. Our PBFS aims to overcome this problem by bounding work memory within available physical memory. PBFS can also be used in combination with paging systems to handle out-of-core input/output more efficiently.

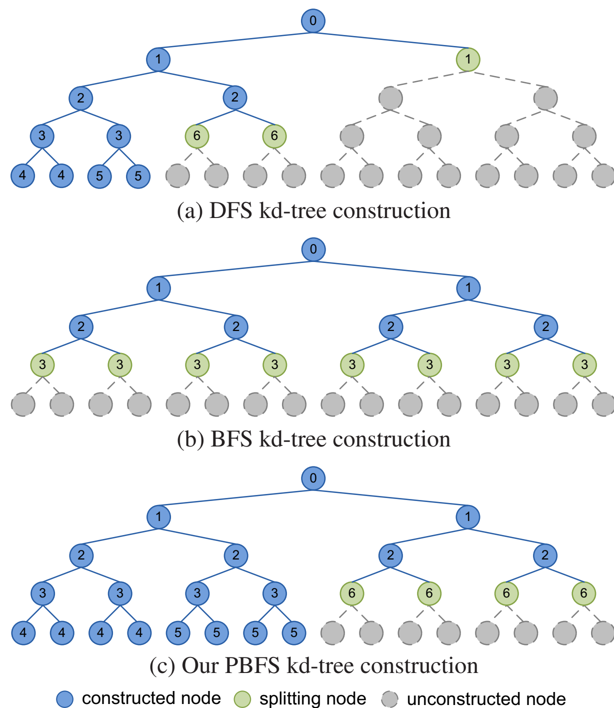

Figure 2: *Different kd-tree construction orders. The number in each node corresponds to the iteration it is created in.*

Memory-bounded situations have been investigated in traditional parallel programming research [Sun and Ni 1993]. The main focus there is the tradeoff between data replication and communication in distributed systems. Our work controls peak memory usage by limiting the creation of new data and does not involve data replication.

3 Memory-Scalable KD-Tree Construction

Most CPU-based kd-tree construction methods follow the natural DFS order. While the DFS order has a small memory footprint, it is difficult to achieve good scalability on more than a few hundred of threads. GPU-based constructors follow the BFS order [Zhou et al. 2008; Lauterbach et al. 2009]. The BFS maximizes the number of nodes constructed simultaneously and thus benefits from the high parallelism of the GPU to outperform DFS methods. However it also results in a significantly larger memory footprint.

During kd-tree construction, each node being split requires storage of extra temporary data for the subsequent computation. Thus, the memory consumption is proportional to the number of nodes being split simultaneously. Based on this, we can make a rough comparison of the memory cost between DFS and BFS schemes. Fig. 2 illustrates the set of splitting nodes maintained simultaneously in three construction schemes. The number of splitting nodes with the DFS scheme is proportional to the current construction depth, as shown in Fig. 2(a). For a scene with n primitives, this depth is $O(\log n)$. In a BFS constructor, the number of splitting nodes grows exponentially with the construction depth and eventually reaches $O(n)$. This is shown in Fig. 2(b). This kind of extreme difference leads to a heavy storage load for the BFS construction scheme.

We introduce a novel partial breadth-first search (PBFS) solution to compromise between parallelism and the size of the peak memory footprint. We control the peak memory by tuning the number of nodes being split simultaneously. Compared to the exhaustive

BFS, the PBFS only splits part of the nodes at a time. This is illustrated in Fig. 2(c). When some trunks of the tree are completely constructed, the corresponding memory is released so that we can split the remaining nodes.

In the following, we first briefly review the BFS-based construction algorithm of [Zhou et al. 2008] in Section 3.1. We then present our PBFS scheme in detail in Section 3.2. Our anti-fragmentation dynamic buffer management scheme is introduced in Section 3.3. Section 3.4 describes how we handle memory issues related to triangle clipping.

3.1 Review of BFS KD-Tree Construction on GPU

The GPU kd-tree construction in [Zhou et al. 2008] mainly consists of two stages. The nodes are divided into two categories, large nodes and small nodes, and are split with different schemes. A node is categorized as large if the number of triangles it contains is greater than a prescribed threshold; otherwise, the node is small. The kd-tree construction starts from the root node. First, a large node stage is launched to split all large nodes recursively. Small nodes generated by splitting large nodes are stored in a dynamic buffer. After dividing all large nodes, the large node stage terminates, outputing a buffer of small nodes. Then a small node stage is launched to finish the construction by splitting all small nodes recursively. For each large node, which contains more than 64 triangles, the median splitting and "empty space maximizing" are employed to minimize the traversing cost of ray tracing. After node splitting, each triangle intersected by a splitting plane is clipped into two polygons (called *clipped triangles* in the following) and distributed to the child nodes. A dynamic buffer is required to hold the vertices of all the clipped triangles generated in the large node stage. For each small node, which contains no more than 64 triangles, the splitting plane is determined to minimize the SAH cost to minimize the traversal cost. Triangle clipping is not performed during the small node stage. Each triangle intersected by the splitting plane is simply distributed to both children.

The SAH cost function is defined as:

$$SAH(x) = C_{ts} + (C_L(x)A_L(x) + C_R(x)A_R(x))/A,$$

where C_{ts} is the constant cost of traversing the node itself, $C_L(x)$ is the cost of the left child given a split position x and $C_R(x)$ is the cost of the right child given the same split. $A_L(x)$ and $A_R(x)$ are the surface areas of the left and right children respectively. A is the surface area of the node. $C_L(x)$ and $C_R(x)$ are usually evaluated as the number of triangles in the two children. For each small node, the splitting plane candidates are restricted to planes containing the faces of the axis-aligned bounding boxes (AABBs) of the clipped triangles contained in the node.

[Zhou et al. 2008] also provides a data structure for storing the triangles in small nodes as bit masks. All small nodes whose parent nodes are large nodes are called small roots. The triangle set contained in each small node is then stored as a bit mask representing a subset of its small root. For each small root, the triangle sets contained on both sides of each splitting plane candidate are also precomputed as bit masks. For each small node, with its triangle mask and the precomputed split triangle sets of its small root, $C_L(x)$ and $C_R(x)$ can be computed efficiently with bitwise operations.

3.2 PBFS Construction

Note that in the above kd-tree algorithm, small nodes consume much more memory than large nodes because the number of small nodes is much greater than that of large nodes. In particular, the precomputation data of all small roots consume most of the temporary

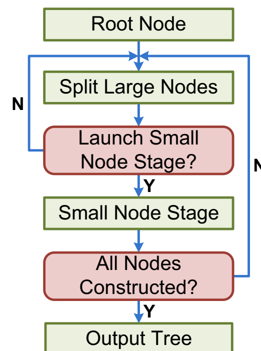

Figure 3: *Our alternating kd-tree construction pipeline: the large node stage and small node stage are launched in alternation.*

data in the tree construction. Because the data of each small root are needed by all of its descendant nodes, the data can only be freed after all descendants of the small root are completely constructed. Therefore, the key point to consider in designing the PBFS strategy is to find an inexpensive way to control the number of small nodes (including small roots) being processed simultaneously.

Our solution is to alternate between large node and small node construction, as shown in Fig. 3. Our observation is that it is unnecessary to wait until all small roots are generated since the small roots are continuously generated throughout the large node stage. At any time if we find the small roots are too numerous to be split simultaneously, we should launch a small node stage to complete the construction of as many small roots as available memory allows. After this visit to the small node stage, all temporary data associated with the completed nodes are discarded. We can then return to the large node stage to continue generating small roots.

The above solution needs to compute the maximal number of small roots that the algorithm can process simultaneously under a memory bound. In other words, we need to compute the memory cost for building the subtree under a small root. Unfortunately, there is no theoretical peak memory usage for the SAH-based kd-tree construction because the tree depth is uncertain. We thus need a tight estimation. Observing that the precomputation data of small roots take most of the peak memory usage, we calculate the size of precomputation data exactly and estimate the remaining memory usage as a constant factor times the number of small roots. We set this factor to a very conservative value at first and update it after each launched small node stage. The number of small roots that can be handled under a memory bound can be easily computed by dividing the memory bound by the estimated per-node memory usage.

Each small node stage begins with the estimated number of small roots to handle. If the number is overestimated and the stage fails due to insufficient memory, we rollback all operations completed during this stage and try again with half of the original small roots. While this approach is robust, the rollback mechanism is costly. In practice, we find that the memory cost estimation is accurate enough to entirely avoid the costly rollback in all our experiments.

3.3 Dynamic Buffer Management

Dynamic buffers are constantly used throughout the kd-tree construction process for maintaining splitting nodes and storing constructed nodes. They inevitably lead to memory fragmentation. If there are a few memory fragments left in the middle of an available memory region, allocating a large buffer could fail, as often happens when working on large scenes. Therefore, we need efficient dynamic buffer management to reduce fragmentation. For this pur-

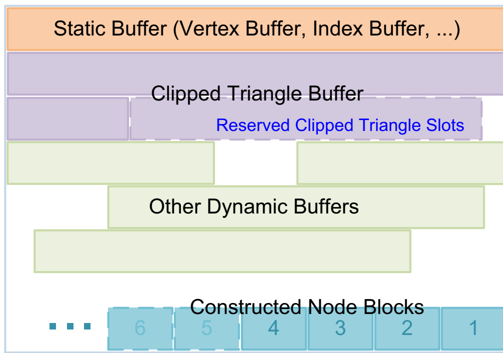

Figure 4: *Memory pool layout in our dynamic buffer management scheme.*

pose, we reserve all available memory as a pool at the beginning of the kd-tree construction, and allocate memory from the pool using special strategies.

We compactly place all static buffers, such as the vertex buffer and the index buffer, at the beginning of our memory pool. For special reasons to be explained in Section 3.4, we also allocate the buffer of clipped triangles statically, even though it is a dynamic buffer.

The most important dynamic buffer is the buffer of constructed nodes. This buffer is continuously appended throughout the entire construction process and cannot be discarded. Without special handling, allocations made for this buffer can cause permanent memory fragmentation. We observe that the nodes deposited into the buffer are left untouched until the construction is complete. This observation allows us to apply a block-based strategy. We allocate the constructed nodes buffer in 4 MB memory blocks from the high address end of the memory pool. When construction begins, a block is allocated at the highest address. When the buffer becomes full, we allocate another block compactly before the previous one. Allocations for all other dynamic buffers are performed at the low address end. The result is that, as long as the memory pool is not used up, the management of the constructed nodes buffer does not interfere with other memory allocations. This is illustrated as the cyan blocks in Fig. 4.

3.4 Efficient Storage of Clipped Triangles

The large node stage also takes a considerable portion of the memory because of the clipped triangles contained in the nodes. As shown in Fig. 4, all of these triangles are kept in a buffer. Nodes only maintain the indices of their triangles. Since we clip triangles to nodes, newly clipped triangles may be added during construction. Therefore, the triangle buffer has to be appended on the fly. Instead of dynamically appending this buffer, we pre-allocate a static buffer with sufficient size for all triangles.

The triangle buffer differs from the constructed nodes buffer in our PBFS scheme. After precomputation of each small node stage, the clipped triangles contained in already-processed small roots are no longer useful. We can label them after each small node stage and reuse the freed memory slots later. As shown in Fig. 5, three slots are freed after a small node stage. These slots are then reused to store new clipped triangles generated during subsequent triangle clipping. Also, this buffer does not grow as rapidly as that of the constructed nodes. For typical scenes, the analysis in [Wald and Havran 2006] shows that splitting a node with k triangles generates $O(\sqrt{k})$ clipped triangles. By adding up clipped triangles generated at all $O(\log n)$ tree levels, the total number of generated clipped triangles can be expected to be $O(n)$, where n is the number of original triangles. These facts make it more attractive to allocate the triangle list buffer statically. In practice, we find a static triangle list with the capacity of $1.5n$ triangles is sufficient for our test scenes.

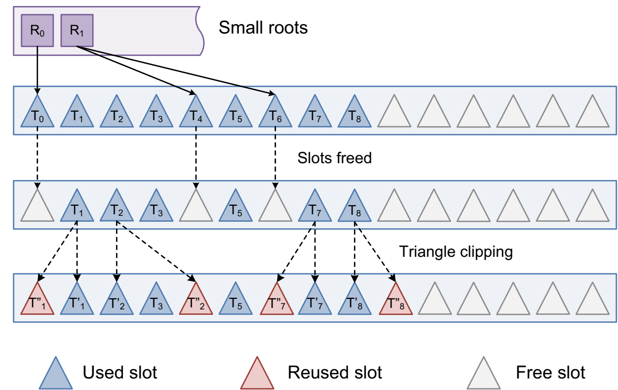

Figure 5: *Reusing the clipped triangle slots. Three slots are freed after a small node stage. These slots are then reused to store new clipped triangles generated during subsequent triangle clipping.*

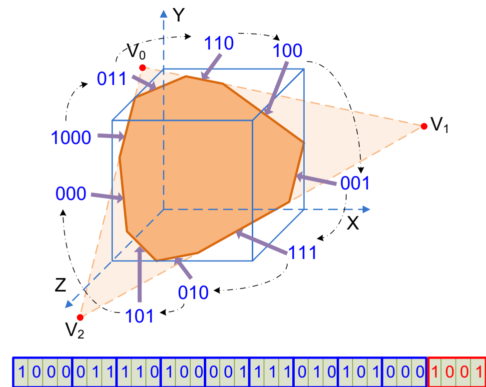

Figure 6: *Packing a clipped triangle shape into a 32-bit integer.*

Slot reuse is only possible if the information for each clipped triangle can be stored in a fixed-size format. Note that we store the current shape of each clipped triangle. This shape is a triangle-AABB intersection, therefore a convex polygon of 3 to 9 vertices. Special handling is required to pack it in a compact fixed-size format.

A triangle clipped by axis-aligned planes will result in a polygon with no more than nine vertices and no more than nine edges. The nine edges can come from the original three edges and the six faces of the AABB. We encode each edge as a 3- to 4-bit binary number. Edges of the AABB are labeled from 000 to 101. The three original triangle edges are labeled from 110 to 1000. The total number of the edges is packed in the four least significant bits. The edge labels are placed from the most significant bits to the least significant bits in either clockwise or counterclockwise order. If the clipped triangle contains the 1000 edge, this edge is always placed in the four most significant bits. Fig. 6 illustrates the packing of a 9-edged clipped triangle shape. Since there cannot be two edges with the same label in a polygon, this 32-bit integer is enough for us to recover all edges and vertices of a polygon given its original vertices and the AABB. With this representation, a clipped triangle only needs to keep the AABB, the edge integer, and the index of the original triangle. This representation only takes 32 bytes per triangle and significantly reduces the memory cost. The reconstruction of vertices does not slow down the triangle clipping because of the reduced memory fetching.

3.5 Tree Output

When building the kd-tree with a given memory bound, the output process of the constructed tree merits a bit of discussion. In [Zhou et al. 2008], the constructed tree is converted into a pre-order traversal format. However, this conversion is itself a BFS traversal. At its memory peak, the original constructed tree, the pre-order traversal, and the node correspondence between them coexist in the memory. This peak is considerably larger than the memory peak in our PBFS construction and has to be avoided. Also, the finalization algorithm of [Zhou et al. 2008] has relatively strict requirements on the processing order of tree nodes and does not fit well in our PBFS scheme.

We chose to use our natural construction layout directly as the final tree node layout and omit the conversion altogether. In theory, our layout may cause a degradation in ray tracing performance. In practice, we found such degradation to be minor. Additionally, this format change allows us to omit the finalization step in [Zhou et al. 2008], resulting in slightly faster tree construction as discussed in the next section.

4 Out-Of-Core BVH Construction

In this section, we describe how to use the PBFS construction order to extend the hybrid BVH construction algorithm proposed by [Lauterbach et al. 2009] to handle very large scenes. The underlying approach consists of two steps. First, several coarsest tree levels are constructed in a bootstrap pass to generate sufficient parallelism, using Linear Bounding Volume Hierarchy (LBVH), a spatial Morton codes based algorithm. Next, the remaining tree is then constructed in BFS order using SAH based strategies.

There is a significant difference in memory footprint between BVH and kd-tree construction. BVH construction does not split triangles or create duplicate triangle references. Consequentially, the primitive storage remains static throughout the whole construction and the final tree size can be bounded prior to construction. Based these observations, Lauterbach et al. [2009] only allocate memory for primitives and the final tree at the beginning of the construction algorithm. Node splitting and triangle sorting are done in-place and little temporary memory is required for construction. While the memory overhead is relatively small, Lauterbach et al. [2009] still cannot build trees that are too large to be stored in the GPU memory (e.g. up to 1.5M triangles on a 1GB GPU). An out-of-core solution is necessary to handle such large scenes.

Our BVH construction also consists of two phases. First, all primitives are loaded into the GPU memory and the AABBs are computed. The bootstrap pass and a few SAH iterations are performed to generate an initial list of a few thousand splitting nodes. All the AABBs are sorted in-place to match the order of their containing nodes. After that, the AABBs and constructed nodes are dumped to the CPU memory and all GPU memory occupied by phase one are freed.

In the second phase, we iteratively copy continuous portions of the splitting nodes and the AABBs of primitives contained in these nodes to the GPU, and construct sub-trees for these nodes. At the end of each iteration, the constructed sub-trees are dumped to the CPU memory and the primitive AABBs are freed. We bound the memory consumption of sub-trees construction using the total number of primitives in the constructed sub-trees. This bound is then used to maximize the number of sub-trees constructed simultaneously in each iteration, just like in Section 3.2.

5 Results and Discussion

We have implemented the described algorithms in CUDA on a workstation with Intel Xeon dual-core 3.0 GHz CPU and an NVIDIA GeForce GTX 280 graphics card with 1 GB of memory.

KD-Tree Construction In Fig. 7, we show six test scenes with different scales ranging from 200K to 7M triangles. On our hardware, the kd-tree builder in [Zhou et al. 2008] can only handle the Fairy Forest scene. It fails with the other five scenes due to excessive memory consumption. Our PBFS scheme improves the scale of scenes by approximately one order of magnitude. In terms of performance, [Zhou et al. 2008] constructs the Fairy Forest scene in 0.065s and achieves a 0.125s tracing time. Since this scene can be processed in pure BFS order, our algorithm automatically degenerates to a two-stage construction and achieves comparable performance as shown in Table 1. The slight difference is mainly due to the fact that we do not convert the constructed tree to a pre-order traversal. Note that even in this scene, our PBFS scheme has a lower peak memory consumption than that of [Zhou et al. 2008] (68 MB vs. 123 MB). This is largely due to our efficient clipped triangle

storage as described in Section 3.4.

In Table 1, we compare our algorithm with the state-of-the-art multi-core CPU kd-tree algorithms [Shevtsov et al. 2007; Soupikov et al. 2008]. As shown, our algorithm can achieve comparable tree construction performance to these methods while providing higher quality trees with less ray tracing time.

An important feature of our algorithm is that, instead of using up all available GPU memory, the user can choose to specify a memory bound for kd-tree construction. In many practical applications, not all GPU memory can be used for tree construction – some memory has to be reserved for other data (e.g., animation data) or tasks (e.g., simulation). Our memory scalable algorithm is very useful in these types of situations. We tested three scenes under different memory bounds as shown in Table 2. "Unbounded" means the memory bound is taken as all available GPU memory, namely the total GPU memory minus the memory reserved for scene geometry, rendering, and the operating system. As the memory bound decreases, the construction has to be split into more small node stages to reduce peak memory consumption and results in less parallelism in individual small node stages. For small scenes, this causes underutilization of the GPU, and slows down construction performance. For the Dragon scene, restricting the memory bound to less than half of the memory peak in the unbounded case results in a 10% performance loss. However for larger scenes, even a small fraction of the intrinsic parallelism is sufficient to achieve full GPU utilization. For the Blade and Neptune scenes, the performance loss is only about 6%.

We also tested our kd-tree algorithm using the two large animated scenes shown in Fig. 1. The falling objects animation in Fig. 1(a) has gradually increasing scene complexity beginning with 560K triangles and reaching 7,140K in the end. This scene demonstrates

how our performance and memory consumption changes with respect to the scene complexity. As illustrated in Fig. 8(a), the memory peak of our construction algorithm exhibits a two-phase behavior. When the scene is small and can fit into the available memory, the peak grows rapidly at a roughly linear speed. As the scene becomes larger, our PBFS scheme takes effect and the memory peak oscillates at a relatively steady level. As the scene size increases further, the memory consumed by the scene geometry increases and the memory available for kd-tree construction decreases. Our construction algorithm thus reduces its memory peak accordingly. Regardless of the memory peak behavior, our construction time grows linearly with the number of triangles, as shown in Fig. 8(b). The PBFS scheme successfully controls peak memory consumption with minimal performance penalty.

The example in Fig. 1(b) demonstrates the potential of our method in handling large animations. The scene geometry and animation consume 248 MB GPU memory. Excluding the memory reserved for rendering and the operating system, only 650 MB memory on the GPU is available for kd-tree construction. Our algorithm can handle that well and achieves interactive performance. Each frame takes approximately 1.84 seconds to render: the kd-tree construction takes about 1.46 seconds, and the remaining time is spent on ray tracing, shading, and animation preparation.

BVH Construction Fig. 9 shows three test scenes which cannot be handled by the in-core BFS-based algorithm [Lauterbach et al. 2009] due to the large memory consumption of geometry and the final tree. [Lauterbach et al. 2009] only handled scenes with less than 2M triangles, while our out-of-core algorithm can support scenes with up to 20M triangles. For all scenes, our constructed BVHs offer similar rendering performance to the reference results which correspond to the full SAH-based BVHs [Wald 2007].

Note that for the same tree quality, our out-of-core BVH construction is still slower than the in-core algorithm running on a 8-core CPU with 16GB memory [Wald 2007]. Our main focus is to push the state of the art in the hierarchies that can be built by GPU-based algorithms, base on memory efficiency. In the future, we plan to use the CPU to construct a portion of the nodes in parallel with the GPU. Significant potential improvement may be achieved if workloads can be efficiently balanced between the CPU and GPU.

6 Conclusion and Future Work

We have presented two GPU algorithms for constructing spatial hierarchies with controllable memory consumption, one for in-core kd-tree construction and one for out-of-core BVH construction. Both algorithms are based on the novel PBFS construction order, and can handle scenes several times larger than previous GPU methods. The construction time is comparable with the state-of-the-art multi-core CPU methods and our tracing performance outperforms these methods.

The PBFS scheme provides an effective approach for balancing memory usage while exploiting the parallelism in general purpose GPU computation. In the future, we would like to apply this scheme to other GPU algorithms in scientific computations and related applications. Although promising, our kd-tree algorithm still has some limitations – it does not control the final tree size. To cope with available memory less than the tree size, tree-size-controlling techniques as in [Wachter and Keller 2007] have to be incorporated into our PBFS scheme.
